Adding multiple smaller wetlands to the landscape can make large reservoirs more effective at flood control, according to a new [study](#) from Tulane University published in [Environmental Research Letters](#).

Using the Brazos River basin in Texas as a case study, researchers modeled more than 140 wetland scenarios and compared performance against existing dams. They found a series of decentralized wetlands provide significant cumulative flood reduction and additional storage.

“Our analysis provides science on how to plan nature-based solutions to improve efficiency of built infrastructure,” said lead investigator [Reepal Shah](#), a research scientist at [Tulane University’s Bywater Institute](#). “Properly sited wetland portfolios can provide comparable flood mitigation on a per-storage basis.”

Key findings of the study include:

- Multiple small wetlands offer greater cumulative benefit than a single large wetland of the same total area, highlighting the value of distributed natural infrastructure.
- Wetlands ranked by flood storage capacity and sequentially added to portfolios provide diminishing returns after approximately 30 sites, indicating not all wetlands perform equally.
- The top 18 wetlands could expand the basin's flood pool by 10% of the largest reservoir's capacity, showcasing wetlands' potential as complementary storage.
- An index comparing impact per unit storage found well-designed wetlands efficacy is comparable to existing dams in flood control efficacy.

"This suggests wetland construction may relieve pressure on aging reservoir systems if done strategically," said [John Sabo](#), co-author and director of the Bywater Institute. "The findings can help practitioners identify robust wetland portfolios to sequence implementation and maximize gains."

The modeling framework couples established land surface and hydrodynamic models to assess flood mitigation outcomes under different wetland scenarios. The researchers plan to further refine the approach and engage stakeholders on utilizing natural infrastructure to improve basin flood resilience.

The findings have important implications for flood management strategies globally. By incorporating strategically placed wetlands into existing infrastructure, communities can enhance their resilience to flooding events. This approach not only provides additional flood storage capacity but also promotes the preservation and

restoration of natural ecosystems.
